## INTRODUCTION

Clark Exploration Consulting of Thunder Bay, Ontario was contracted by Superior Canadian Resources Inc. of Calgary, Alberta to plan, supervise and report on the geophysics survey (Magnetics and VLF-EM) and to incorporate the MMI survey in the report of the Aurum Project. The geophysics was completed on 41 lines over structures east and west O'Sullivan Lake Mine and areas of interest defined by the airborne surveys. The line cutters and technicians and support staff were housed at a trailer camp constructed at the old mine site. Camp operations including room and board were provided by Superior Canadian Resources.

The Aurum Project claims are underlain by Archean metavolcanics of the Wabigoon Belt of the Superior Province. The metavolcanics consist of mafic to intermediate flows and tuffs, which have been locally intruded by felsic dykes, sills and small stocks. All rocks in the area have been sheared or foliated in a north-easterly direction ( $045^\circ$  to  $065^\circ$ ) and there are numerous northeast-trending structures that have acted as conduits for hydrothermal, gold-bearing fluids.

The gold mineralization is consistently associated with quartz veins in or adjacent to quartz and quartz-feldspar porphyries, and occurs as both native gold and associated with sulphides.

## PROPERTY DESCRIPTION and LOCATION

The Aurum Project consists of 27 contiguous, unsurveyed, unpatented claims in the O'Sullivan Lake and Maun Lake Areas (see Table 1). The property is approximately 35 km northwest of Nakina, Ontario, and approximately 300 km northeast of Thunder Bay, Ontario.

The claims are held in good standing by Superior Canadian Resources, and are illustrated on the O'Sullivan Lake and Maun Lake Areas claim sheets (G-0362 and G-0319) N.T.S. 42 L 6/NE and 42 L 7/NW.

Superior Canadian Resources Inc. also has the Consolidated Louanna Mine under option which is comprised of 21 partial patents.

**ACCESSIBILITY, CLIMATE, LOCAL RESOURCES, INFRASTRUCTURE and PHYSIOGRAPHY**

The Superior Canadian Resources Dog Exploration Inc., Aurum Project is located in the O'Sullivan Lake and Maun Lake Areas, Thunder Bay Mining Division.

The O'Sullivan Lake property areas lie approximately 300 km northeast of Thunder Bay, Ontario and 35 km northwest of Nakina (Figure 1). The property is within the Beardmore-Geraldton area of the Thunder Bay Mining Division. The claim map sheets are O'Sullivan Lake, G-362 and Maun Lake, G-319 with latitude 50 27'20" and longitude 87 00'00" in the NTS 42L6NE and 42L7NW.

Access is via Highway 643 from Nakina north to O'Sullivan Lake and branching off on the road to the Consolidated Louanna Mine. From here, a boat will be needed to access the other side of the lake where the claims covering Hurd Lake Fault Zone have been staked.

## PROPERTY HISTORY

Gold mineralization was first reported in the O'Sullivan Lake area by Kindle (1931), who reported the gold on the Cryderman claims (on the west end of the Cryderman Peninsula, west of the current Aurum Project claims) occurred in quartz stringers in sheared porphyry, with associated extensive carbonatization of the adjacent volcanics.

The original claims of the Consolidated Louanna Gold Mine were staked in 1935 by Jack Miller. A shaft was eventually sunk on the property in 1947, on a mineralized zone in sheared tuffs and quartz porphyry. Sporadic work was performed on this property between 1947 and 1983, and in late 1983 production was reported from the mine, with the mill concentrating 190 – 200 tons per day. Production continued until the mill closed in October 1984, with a total of approximately 70,00 tons milled at a grade of 0.22 ounces/ton (Mason and White, 1986).

The area was mapped in detail by the Ontario Department of Mines in 1947 and 1948 by Moorhouse (1956). Recent government work has included an airborne electromagnetic and magnetic geophysical survey in 1989, and mapping by Parker and Stott (1998).

Some of the showings on the current Aurum Project claims have been worked since the 1940's, with work being reported in the MNDM assessment files in 1950. A summary of the previous work is presented in Table 2, and is taken from Moorhouse (1956), and the MNDM assessment files located in the Thunder Bay Resident Geologist's office. Most of the assessment files did not include assay results or certificates since they were not required when the work was done; as a result the values from the older work could not be verified.

## GEOLOGICAL SETTING

### REGIONAL GEOLOGY AND DEPOSIT TYPES

The O'Sullivan Lake area is underlain by an Archean Metavolcanic sequence of the Wabigoon Subprovince. The metavolcanic sequence trends east-west to northeast, dips sub-vertically and youngs to the north. The belt consists of massive to pillow mafic flows intercalated with metasediments and intermediate tuffs overlain by a narrow belt of felsic to intermediate tuffs and metasediments.

Intrusives of mafic and felsic composition are intruded both conformably and unconformably into the volcanics. The mafic intrusives include diorite and gabbro sills and dykes. Felsic intrusives range from quartz feldspar porphyry dykes and sills to small granitoid bodies.

The metamorphic grade of the belt ranges from greenschist facies to upper greenschist-lower amphibolite facies near the granitoid intrusives. The strongest structural imprint on the area is a northeast fabric developed as a regional schistosity and locally as kilometre-scale faults. These faults have been noted by numerous authors and correspond to the northeast-trending lineaments.

The area is covered by a variable thickness of glacial outwash which includes sand, till, and local esker material.

The O'Sullivan Lake Belt is host to the past-producing Lake OSU Gold Mine (Consolidated Louanna Gold Mine). The mine property was first explored in detail in 1935. This work lead to the sinking of a shaft to the 150 foot level in 1947. Extensive but sporadic work was carried out from 1947 until 1984, with overall production of approximately 15 400 ounces of gold. The ore zones of the mine occur within a strongly sheared and altered mafic to intermediate tuffaceous horizon. The tuff horizon is hosted by massive to pillow mafic flows. The tuffaceous band has been the focus of shearing, porphyry intrusion and associated alteration. The intrusions consist of quartz- and quartz-feldspar porphyries, are irregular in shape and size, and are frequently sheared. The alteration of the tuffaceous horizon consists of pervasive carbonate and weak sericite with intense silicification and sericitization near the intrusive contacts.

The mineralization at the mine is associated with bluish quartz veins hosted by the quartz-feldspar porphyries and the sheared tuff. The veins contain up to 15% sulphides (pyrite, pyrrhotite, arsenopyrite, sphalerite, and chalcopyrite) and native gold.

## 2008 GEOPHYSICAL PROGRAM

Superior Canadian Resources completed a magnetic and VLF-EM survey over approximately 40.55 kilometres of cut and ice grid. The grid was oriented with wing lines at 339 degrees. A GSM 19 magnetometer and VLF-EM system was utilized for the data collection. Due to the orientation of the gold mineralized structures a TX 27 transmitter was used to collect VLF-EM data as well as utilizing the transmitter at Cutler, Maine. Todd Maitland completed the geophysical survey from January 22/08 to January 28/08. The line cutting and gridding was completed from June 01/07 to just prior to commencement of the magnetic survey by consulting staff of Superior Canadian. The consulting staff included at various times 2 -3 men crews each working independent of each other under the supervision of the project manager at either end of the grid along with a surveyors assistant and his tools. The total man days accumulated on the grid totalled 1075 covering all personal involved. The geophysical data is presented in Appendix I.

## DISCUSSION OF GEOPHYSICAL RESULTS

The area covered by the ground geophysical survey includes a few lines to the west of the Louanna shaft and an area extending east of there for about 1500m. Further south a larger area was covered within O'Sullivan Lake.

The ten GPS readings of the grid location showed that the grid was well located in the field and on the lake. The grid measurements were excellent and matched up very well. Plotting of the geophysical data was somewhat difficult and time-consuming.

The field crew reported difficulties with the data from the TX-27 transmitter and recommended not using the data. The VLF-EM data for Cutler was used.

The magnetometer data is good and appears to have been well processed. In the lake, it shows a zone of magnetic low to the south, possibly changing to a different geological domain toward the north where a higher magnetic background predominates. A structure shown as a zone of magnetic high trends northeast (#1 on Plate 1) and could possibly represent a diabase dyke, although these dykes generally trend north-northwest. The area near Cryderman Point shows higher magnetometer readings and reflects the gabbroic rocks reported in geological mapping.

Only one subtle feature in the lake could correspond to a magnetic low, possibly indicating hydrothermal alteration and possible injection of quartz porphyry (#2 Plate 1). On the Louanna Grid, several zones of magnetic high may indicate the edges of diabase dykes (#1, 2 Plate 2). The zones of magnetic low may indicate zones of shearing that have been injected by quartz porphyry.

Two such zones of magnetic low are located on the island in the northeastern part of the grid where outcrops of quartz porphyry were mapped. The one at the northern end of the island is on the northern edge of the survey and only a few readings were taken there (#3, Plate 2).

At the southern end of the island a broad elongated magnetic cross cuts at least three grid lines and is oriented parallel to the general strike of the rocks. A large outcrop of quartz porphyry was mapped near this area (#4, Plate 2).

Another zone is present immediately to the south of the island on the south shore, where another elongated magnetic low may represent a zone of shearing and injection of quartz porphyry, rocks that have been associated with gold mineralization (#5, Plate 2). Further west the magnetic patterns are less distinct and may have been complicated by late diabase dykes.

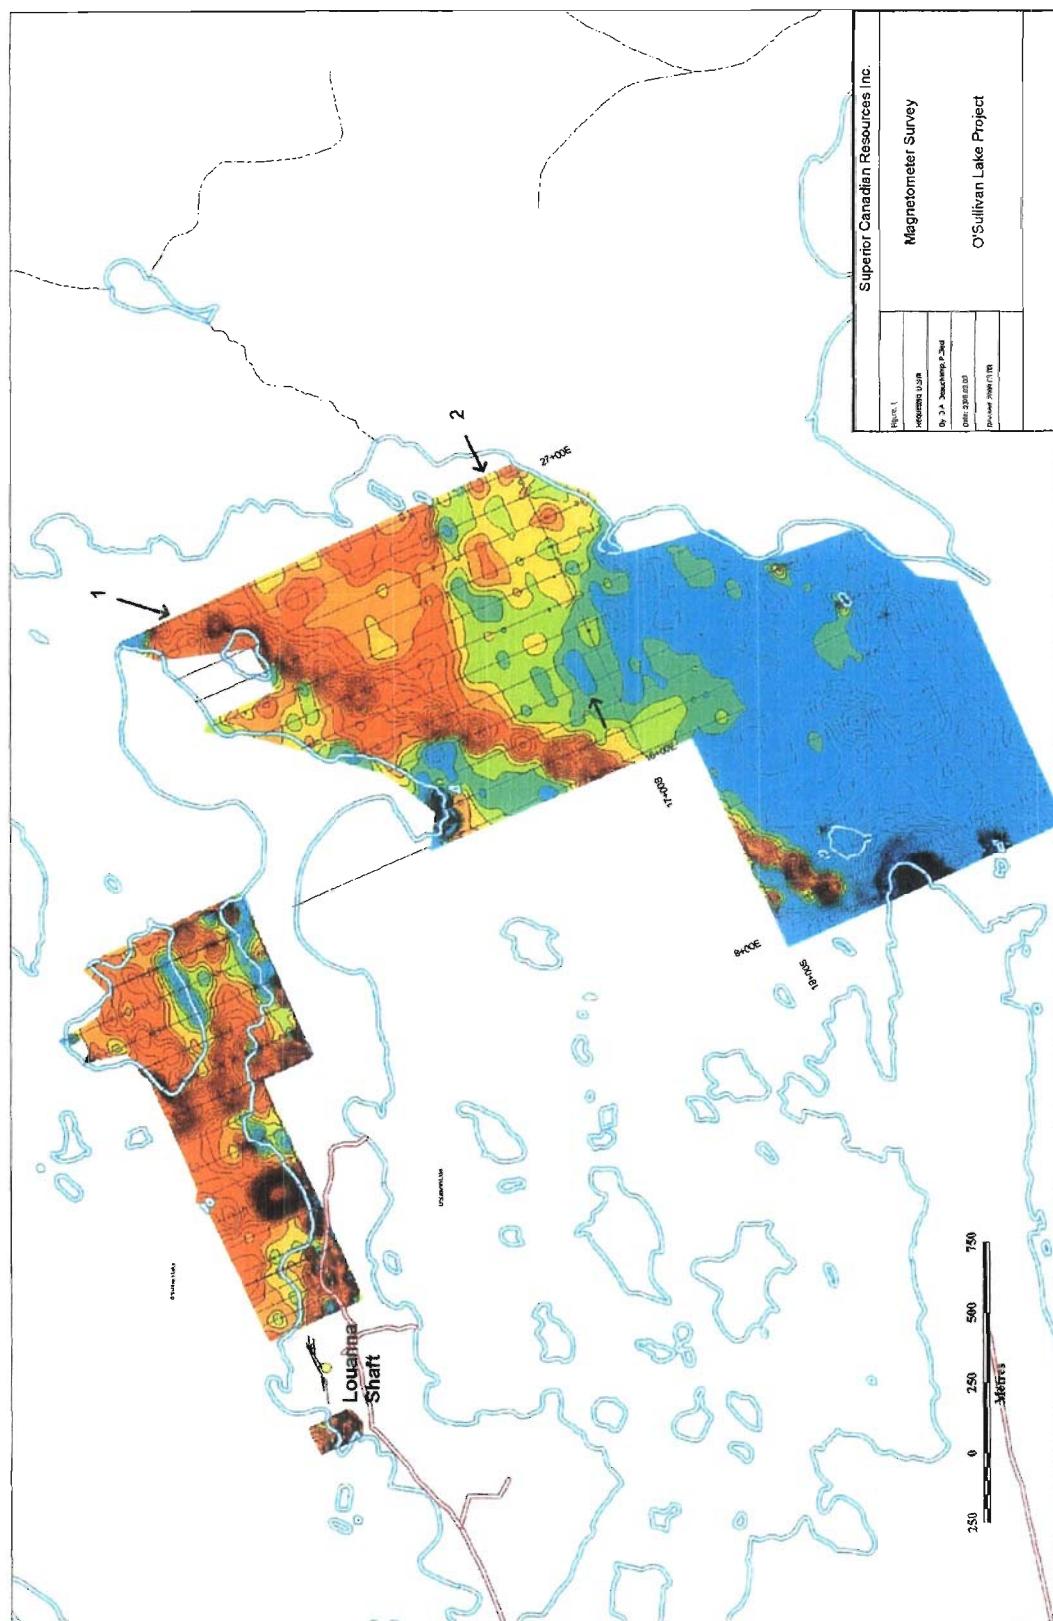

Plate 1

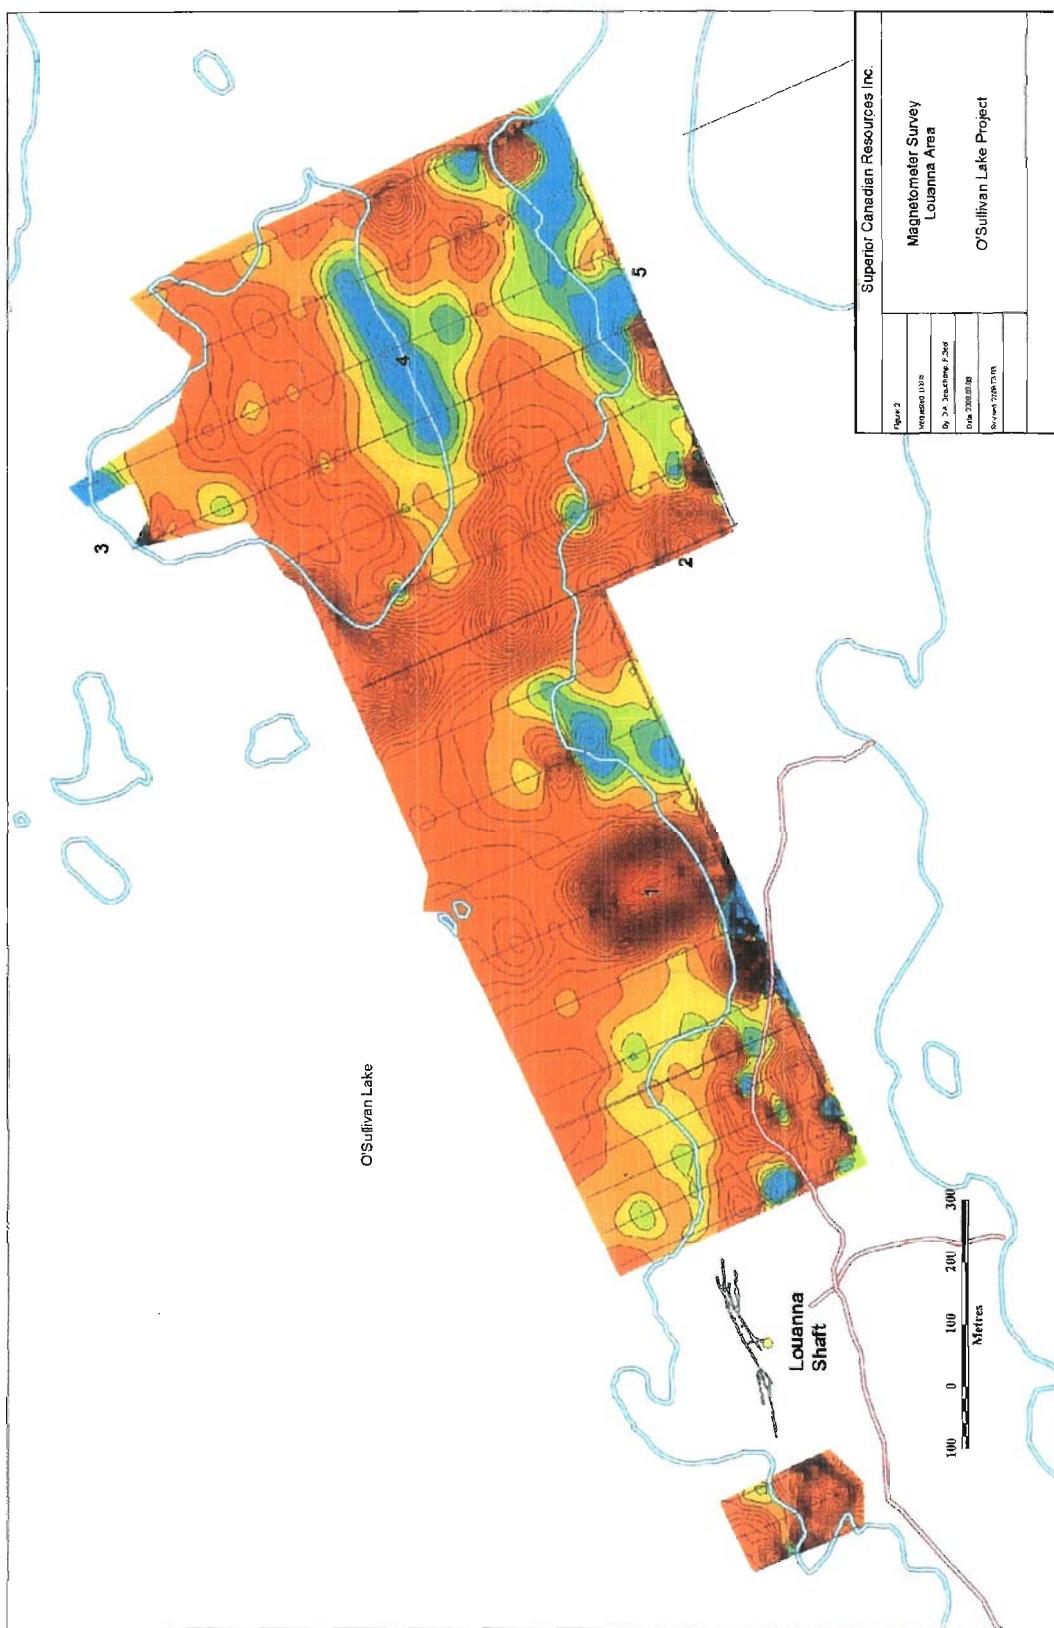

Plate 2

November 2008

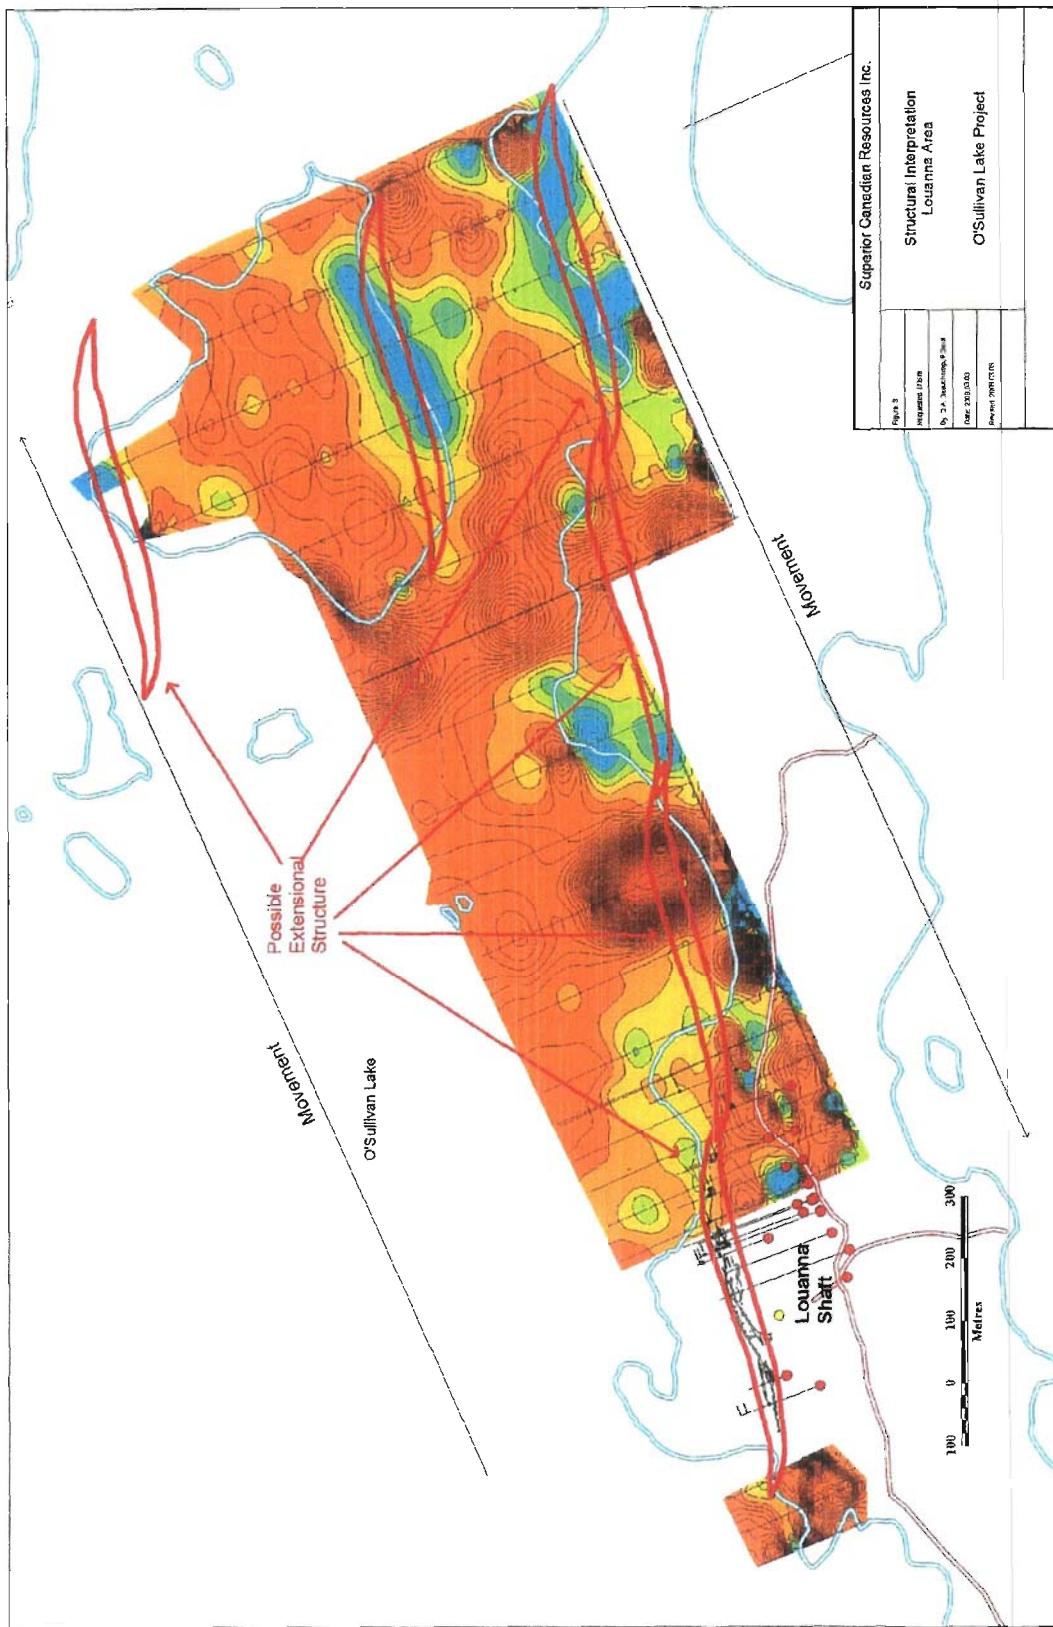

Plate 3

## VLF-EM RESULTS

The VLF-EM survey indicates some short length weak conductors. Numerous cross overs seem to match shorelines and may be shoreline response. The Cutler data is presented in Map 3. The data acquired from the TX 27 transmitter was not deemed as usable for plotting as the values were extreme. The raw data is presented in Appendix I.

## MMI SURVEYINTERPRETATION and CONCLUSIONS

The MMI is presented as Appendix II.

## INTERPRETATION

### Geology

The mafic tuff described in the core is spatially associated with the quartz eye tuff and these two rock types are always found within thick zones of mafic volcanic rocks. It has been suggested that the faulting and shearing may have preferentially localized along the mafic tuff unit.

It is probable that the mafic tuff is the result of extensive shearing of the mafic volcanic rock in a right-lateral extensional terrain, and that this zone of weakness was later intruded by quartz porphyry, described as quartz eye tuff in the current drilling.

In his notes, M. Young also questioned that the mafic tuff horizon may “not a rock type but a deformational texture” (Internal report to Superior Canadian Resources, December 2006).

The mafic tuff horizons were most likely formed by shearing the mafic volcanic rocks and they are spatially associated with the gold mineralization. The voids and zones of weakness in the rock were later injected with the quartz porphyry, or quartz eye tuff. These can appear as zones of magnetic low.

### Structure

Near the shaft at the Louanna Mine, the zone of mineralization and the envelope of shearing surrounding it generally trend at 069°. Further east, the gold mineralization intersected in drill core shows a gradual bending to the southeast (Plate 3, #1).

In plan view, this may well be due to a structure known as a right-lateral zone of extensional shearing in a ductile fault zone. This type of structure is occasionally referred to as a cymoid or as a rhombochasm. This concept is supported by Young in his field notes, who described extensive right-lateral shearing at Louanna.

At Louanna, these extensional shear zones are relatively thin and elongated at the regional trend of 069°, and may be offset en echelon to the southeast. This conforms to the general appearance of the magnetic low shown on the maps.

In longitudinal section, Young describes the mineralization as plunging deeply to the east, although a lineation has been mapped in the area as plunging 55-75° to the west. Other than a general impression that the mineralization appears to plunge to the southeast, there is little geological information to support this view, although this view will continue to be supported until hard evidence is obtained.

## CONCLUSION

- The mineralization and the geological environment are typical of quartz and quartz-carbonate mineralization in Archean volcanic rocks.
- The mafic tuff is more likely a zone of shearing within the mafic volcanic rocks.
- The regional structure is typical of en echelon extensional shear zones striking 069° but may be offset to the southeast.
- The grid should be extended north of the island (#3, Plate 1) before the end of the winter season to determine the full extent and geometry of the magnetic low.
- When diamond drilling resumes, serious consideration should be given to drilling the magnetic lows at #3, #4 and #5 from Plate 1.

## Summary

A soil survey was carried out on the Kowkash area of the O'Sullivan Lake project. The project is located about 80 km north of Geraldton in the Thunder Bay Mining District. Access is by road to the property, and then by boat to the east side of the lake.

A total of 196 samples were collected along six grid lines at a line spacing of 100m in an area underlain by Archean volcanic rocks intruded by Archean granodiorite and feldspar porphyry that was later intruded by Proterozoic diabase.

The samples are processed by simply adding a solution of ligands to the sample and the solution is analyzed for 40 elements by ICP-MS.

The results show a range of values for most elements. Values for gold, copper, silver and cobalt were examined and found to be highly variable from line to line and were difficult to interpret. The correlation coefficients between these elements are very low but the correlation coefficients among rare earth elements are very high.

Because of the inconsistent results from line to line, and of the highly variable values and poor correlation among the elements studied, the data is of not helpful in delineating exploration targets in this area.

## Property Description and Location

The O'Sullivan Lake Property, located in northwestern Ontario in the Thunder Bay Mining District, in NTS 42L06 at about longitude 87°02'30"W and latitude 50°26'30"N (Figure 1).

Access to the property from Geraldton is by road about 62 km north along Highway 584 and then about 50 km northwest of Nakina along Highways 584 and 643 (Figure 2).

From the west shore of O'Sullivan Lake a boat can be used to access the Kowkash area where the field work was carried out.

The O'Sullivan property consists of 27 mineral claims and a group of patented claims (Figure 3). The Kowkash area is located mostly in claims 1242501 and 3012082.

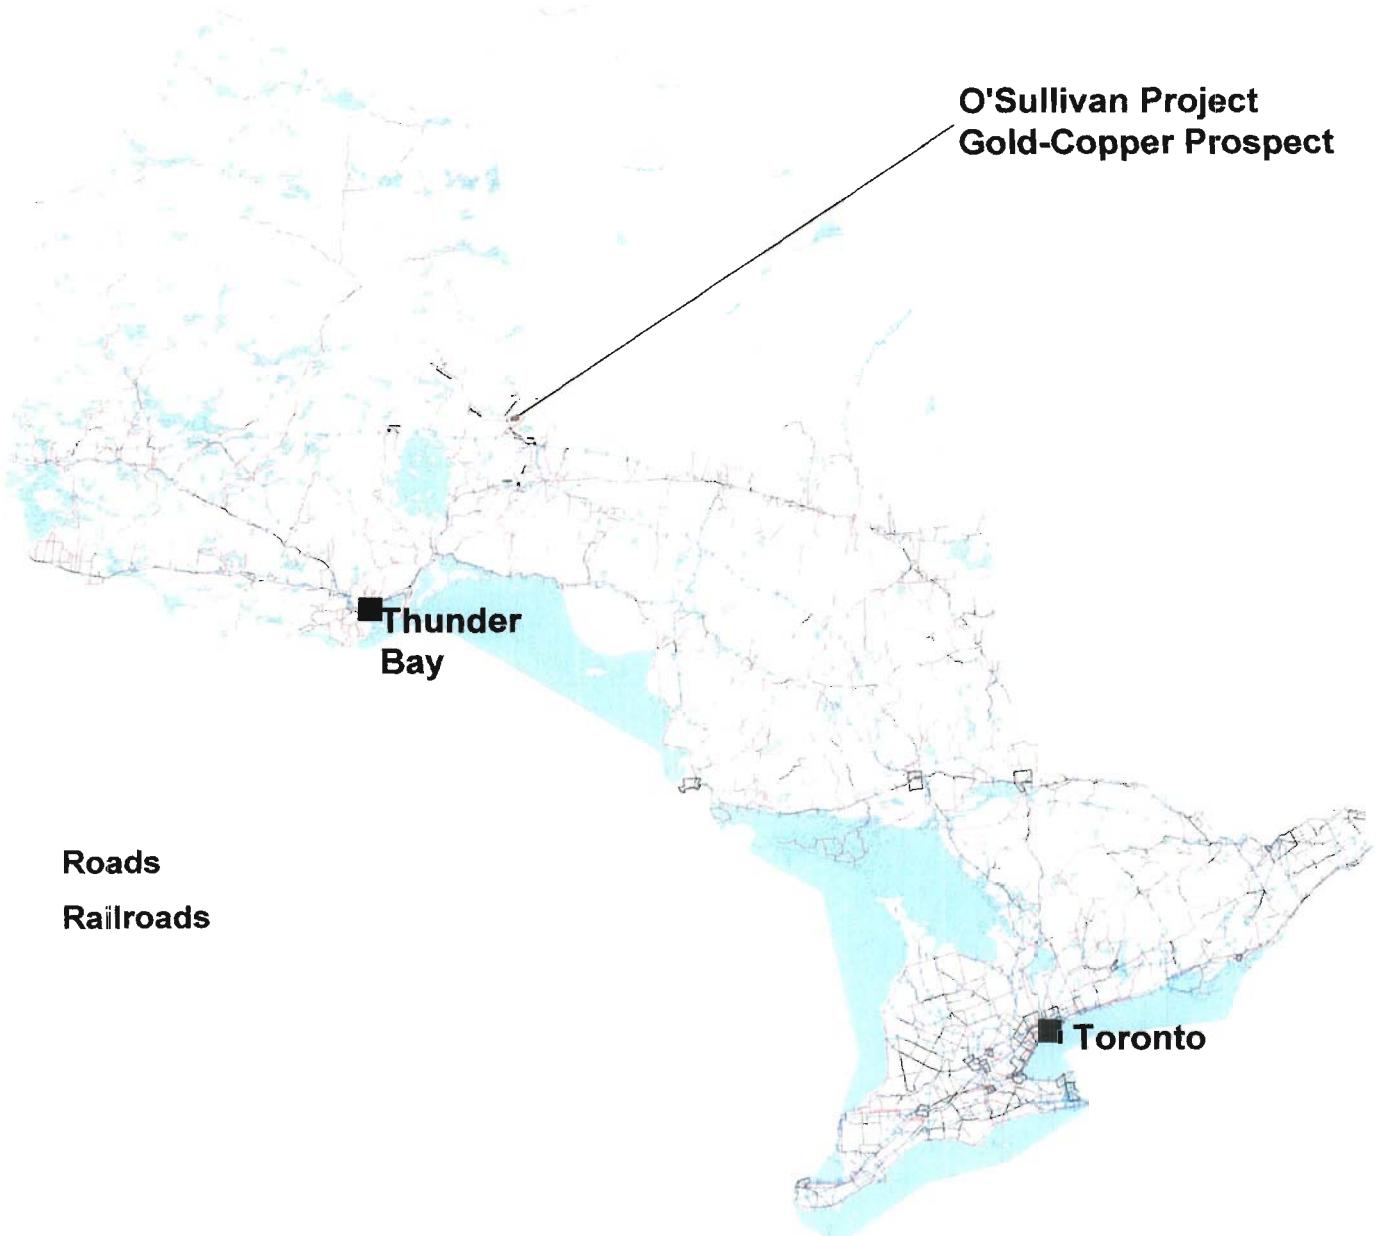

## Work performed

The field work was carried out from September 22 to September 26, 2006 and the samples were shipped to the laboratory in Toronto.

The work was carried out in the field under the supervision of Mike Young, M.Sc. and by Dave Christianson of Thunder Bay. The samples were submitted for Mobile Metal Ions analysis to SGS Laboratories in Toronto.

## Background on Mobile Metal Ions

The procedure for the analysis of mobile metal ion is based on a description from the SGS Minerals Services website, the laboratory company that has been performing MMI (Mobile Metal Ions) analyses for ten years. The technology is an exploration geochemical method for discovering mineral deposits that are covered by overburden.

The **MMI Technology** is a geochemical process that extracts mobile metal ions from the soil samples using weak solutions of organic and inorganic compounds called ligands, instead of the acid- or cyanide-based solutions that are used in conventional analysis.

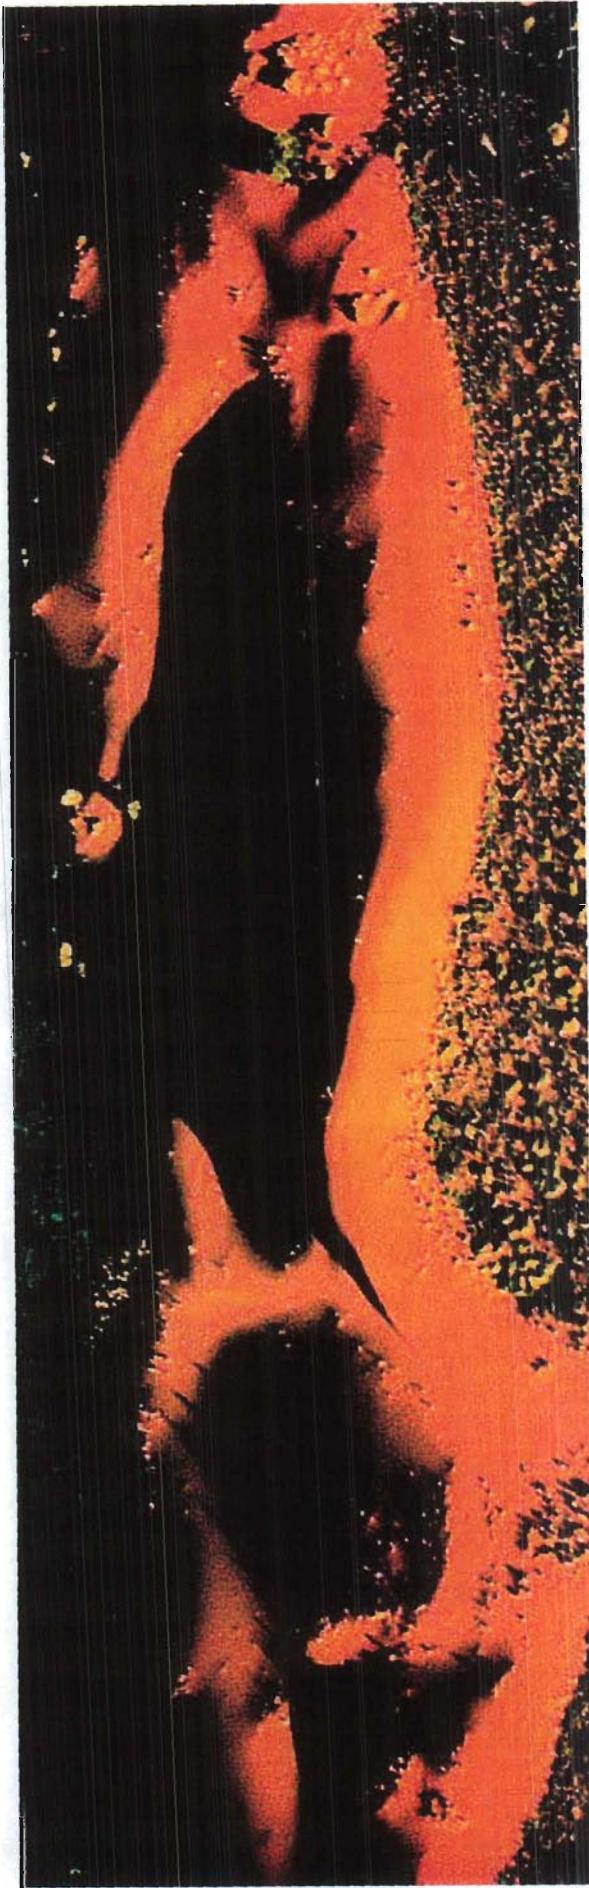

MMI solutions contain strong ligands that are used to separate and place in solution metal ions loosely bound to soil particles by weak atomic forces. The solutions are formulated to avoid dissolving the forms of the metals that are more strongly bound. The metal ions held in solution are therefore the chemically active or 'mobile' component. These mobile forms occur in very low concentrations and are measurable by ICP-MS (Inductively coupled plasma mass spectroscopy).

The **MMI process** includes a specific soil sample collection procedure. At the Kowkash area of the O'Sullivan Lake project, samples were collected at standard depths of 45-60 cm and full sample descriptions were made in the field at the time of collection. The samples were placed in plastic self-closing bags from material that has nor been in contact with metal tools to avoid possible contamination.

During processing, the samples are not processed, prepared or dried. The solution of ligands is added to a soil sample weighing 50g and the extracted solution is analysed by ICP-MS (Inductively coupled plasma mass spectroscopy) for specific elements giving most results in parts per billion.

For this program SGS Minerals Services' **MMI-M Multi-Element Package** was selected resulting in the analysis of the following elements: Cu, Cd, Pb, Zn, Au, Pd, Co, Ni, U, Nb, Rb, Y, Ba, La, Ta, Ce, Pr, Nb, Sm, Gd, Tb, Er, Yb, Ti, Zr, Ca, Mg, Al, Sc, Th, Li, Fe, As, Sb, Bi, Tl, W, Sn, Mo, and Te.

From the field, the samples were shipped to Thunder Bay where they were packaged and sent by truck to SGS Minerals Services' laboratory in Toronto.

## What is MMI Technology® ?

The MMI Technology is an innovative geochemical process that uses a very different approach to the analysis of metals in soils and weathered materials. It involves sample attack using extremely weak solutions of organic and inorganic compounds rather than the conventional aggressive acid digest solutions or fusions. Conventional techniques digest soil substrates releasing metals that are chemically bound by strong atomic forces, either to each other or within and to the clay and other minerals and particles in the soil sample. In contrast to this MMI extractants, containing strong ligands, are used to detach and hold in solution metal ions which are loosely bound to soil particles by weak atomic forces. The extractants are so as to avoid dissolving the bound forms of the metals. The metal ions held in solution are therefore the chemically active or 'mobile' component. These mobile forms occur in very low concentrations that are readily measurable by modern ICP-MS analytical instrumentation with considerable precision, provided that the solution delivered to the machine is very dilute. MMI extractants meet these criteria particularly well.

The mechanism of formation of MMI anomalies has been the subject of industry and government sponsored research between 1993 and 1997 at the Geochemistry Research Centre in Perth, Western Australia. Under the auspices of the Minerals and Energy Research Institute of Western Australia, this research has led to an improved understanding of how MMI soil geochemical anomalies form, for a wide range of weathered materials, climatic conditions and countries. Together with the results of many hundreds of unpublished case studies and exploration programs, this work suggests that metal ions are released from mineral deposits by oxidation process at depth, migrate essentially vertically and concentrate in the soil profile close to the surface, overlying their source. These 'mobile ion' anomalies are interpreted as the pre-cursors to the conventional or 'bound' geochemical responses that form broader patterns, usually with lower anomaly-to-background resolution, and in some cases transported from the primary source. By deliberately targeting only the recently arrived or mobile forms of metal elements, prior to chemical binding and their chemical and physical dispersion over the landscape, MMI analyses give a more focussed geochemical expression of buried mineralisation, even in many types of transported overburden at low detection levels.

MMI Technology offers proprietary extractants. "MMI-A" is a weakly buffered acidic leach for soil analysis for copper, lead, zinc and cadmium. "MMI-B" is a weakly buffered alkaline leach for soil analysis for gold, silver, nickel, cobalt and palladium. "MMI-F" (pathfinders) measures arsenic, antimony, mercury, molybdenum, selenium and iron. Special extractants for kimberlites, "MMI-D", analyses for nickel, cobalt, palladium, niobium, chrome, magnesium, caesium, rubidium and yttrium (lithochemical discriminators). "MMI-G" analyses for pegmatophile elements, specifically uranium, thorium, lead, tantalum, tin, tungsten and lithium. "MMI-C" was developed for base metal analysis in highly alkaline soils and "MMI-L" is designed for precious metals in super absorbent and saline samples e.g. for exploration over salt lakes, black soils and humus rich terrains. "MMI-M" is a new, single multi-element leach that now provides an option to measure the concentration of a broad selection of mobile elements in soils. With MMI-M, explorers can now create their own individual multi-element packages, using any or all of commodity elements, diamond host rock elements, lithological elements and pathfinder elements.

The technology is licensed to two of the largest analytical laboratories in Australia (ALS Chemex) and Canada (SGS Group) respectively. Both have global operations capable of providing the required analytical performance and logistical service required.

## Development of MMI Technology®

MMI Technology was first made available to the exploration industry research sponsors in 1992. By 1994 it had been tested at over 74 different base metal or gold deposits with remarkable success (Mann et al., 1995). Sharp and responsive commodity metal anomalies over concealed deposits of copper, lead, zinc, nickel and gold were defined at all but 10 of these 74 sites, which occur in a range of geographical environments, from arid to high rainfall, and including deeply weathered terrains and areas covered by transported overburden. This is a success rate of 86%. The success rate of conventional soil geochemistry has not been accurately measured but, given the common failure of total digest analysis in alluvial and aeolian cover, is significantly less, probably less than 20 percent.

In addition, an extensive set of applications research data from many hundreds of mines, deposits and exploration camps around the world has been accumulated. The success rate remains above 80 percent. Most of this data is confidential to the mining companies involved. However those that are in the public domain illustrate the application of the technology in a wide range of geological, geographical and climatic environments. Currently the technology is being applied in numerous countries world-wide, and several companies have published results of surveys in what are geochemically difficult terrains in respect of conventional geochemical methods.

The MMI Technology is particularly reliable and applicable in areas which have a well developed soil layer. In areas of certain Indonesian islands which are widely covered by metres of tephra, the technology has been tested at 28 sites of variable tenors of buried mineralisation defined by extensive drilling to about 150 metres depth (Fripp, 1999). The success rate for MMI was 90 percent. MMI gold results accurately located the site of the buried mineralisation at all the sites where it would rank as a resource. In particular it did not highly rank the weak and modest mineralisation which drilling had shown would not be sufficiently continuous or robust to warrant extensive drilling for a resource. This drilling was focussed at Total Digest gold-in-soil anomalies of similar strength to those at the strongly mineralised sites. Had MMI extractants been used initially the weakly mineralised sites would not have been drilled, leading to very significant cost savings. This is partly because the MMI Technology is not prone to the nugget effect responsible for the misleading Total Digest anomalies. The incidence of false anomalies is very significantly less than that for conventional soil geochemistry.

In Manitoba Province, Canada, the technology has successfully identified a new VMS style base metal prospect (Assean Lake Prospect), and a new gold camp (Hunt Gold Project) which is adjacent to the base metal mineralization (Fedikow, 2002). Drilling has successfully tested both. Key to these successes has been the development of reliable ultra low levels of detection, particularly for gold, that allows definition of natural backgrounds in transported or exotic overburden. Field trialing in highly transported surface environments has been undertaken and includes salt lakes in the Eastern Goldfields, WA and glaciated till covered terrains in Canada. This work has shown that it is now possible to identify the very low 'natural background' levels expected from geochemical data in highly transported soils, rather than 'machine imposed' background levels available previously. The data is robust, repeatable and now routinely available commercially and provides explorationists with a tool to explore more confidently in transported soil terrains.

Sampling is simple but critical for successful application. Soil samples MUST NOT be processed, simply placed in plastic bags, and they MUST be collected as an integrated 'channel' sample from 10-25cm below the organic-soil interface. Extensive research information and sampling instructions are available on the web page.

## The Benefits of MMI Technology®

- False and displaced anomalies may occur, but their occurrence is statistically very low compared to conventional geochemistry, thereby reducing drilling costs. By careful planning and interpretation of MMI multi-element geochemistry exploration programmes, it is possible to understand and limit the effect of misleading anomalism;
- Repeatability is excellent. Repeat samples taken at any particular site have very limited variance, less than 15 percent in the case of gold;
- Nugget effects are minimised. The results of all experiments and applications to date has shown that analyses of mixed samples return values very close to the arithmetic average of the separate samples analysed prior to mixing. This makes interpretation of anomalism and the statistical treatment of data more reliable, and reduces the incidence of false anomalies. It also enhances the application of less costly and more reliable composite reconnaissance sampling;
- Focussed anomalies. Anomalies are commonly restricted and narrow, and tend to occur directly above buried primary mineralization, thus sharply defining the area of the drill target, and thus reducing the extent of early drilling programmes by approximately 30% to 50% compared to conventional geochemistry. Sampling is much more rapid and does not require auger drilling, so it is much more cost effective;
- Zonation and metal associations. MMI provides high-resolution data, which is capable of allowing the definition of metal zonation within buried deposits, lithochemical discrimination and specific metal associations, e.g. Zn and Cd in sphalerite, gold selvedges on base metal hanging walls.
- Deeply buried mineralisation is detectable, as demonstrated in many orientation surveys. These surveys done over known deposits have readily detected deposits up to 700 metres below surface;
- Background values are low. MMI anomalism over any deposit or mineralisation is more strongly defined than the corresponding conventional anomalism, with *response ratios* of signal to background much greater than for conventional analysis;
- Lower limits of detection for all of the commodity metals analysed are at least an order of magnitude better than conventional geochemistry, that is one tenth the value, at a comparable to slightly cheaper commercial cost. Accordingly the technology is commonly applicable in leached, deeply weathered terrains, and in areas covered by transported overburden such as sheet-wash, wind-blown sand and glacial overburden, the regions for which conventional geochemistry usually cannot detect a chemical signal at surface;
- MMI anomalies are defined by the commodity metals being sought and the use of pathfinder metals is not required; and
- At fault and shear zone positions the MMI Technology is known to be able to identify elevated and not necessarily anomalous values of certain metals, particularly base metals. This is a no-cost additional benefit of applying the technology because together with geophysical imagery an improved picture of the bedrock geology may be possible, and structures which are "alive" with respect to commodity metals may be discriminated from those that are not.

## *Application of MMI Technology®*

Application of the technology led to discoveries of economic gold mineralisation at the Golden Web Mine and of sub-economic mineralisation at the Forest Prospect, both near Coolgardie in Western Australia. At Nepean, also in Western Australia, MMI Technology was able to define the location of buried nickel mineralisation where conventional geochemistry was ineffective. All of the above deposits occur in arid and deeply weathered laterite terrain, and sample media included soils associated with sheet wash sands, laterite duricrust and degraded lateritic colluvium. In addition the Technology has successfully identified the location of buried gold mineralisation in laterite terrain which, rather than being arid, sparsely vegetated and of low relief like the gold fields of Western Australia, is the hilly, tropical humid jungle of Venezuela. This is the La Salle Prospect near Anococo.

In the rugged wet terrain of central west Scotland at Kilmelford, MMI Technology has identified and discriminated between related bedrock deposits of copper-gold and lead-zinc-silver. Outcrop at Kilmelford is less than 10% despite the rugged terrain and the media sampled was mainly boggy clays, peats and glacial sands. At the Hunt Lake Prospect in Manitoba, Canada and at the Night-Hawk Lake Prospect near the famous Timmins mining camp in Ontario, Canada, MMI technology has successfully identified copper-lead-zinc and gold-silver mineralisation. At these Canadian examples there is no outcrop, conventional geochemistry was completely ineffective, and the results of drilling to date show "ore-grade" mineralisation intercepts which have encouraged the companies to continue deep diamond drilling. The new discoveries are buried beneath up to 30 metres of glacial gravels, sands and lake clays, and the media sampled were mainly wet sandy soils with a high organic content. Recent new Canadian discoveries of gold include the Avalon Dubenski prospect and Hunt Gold Camp, details of which are on the website.

MMI Technology has also successfully located buried mineralisation beneath 70 metres of the desert gravels and sands in the Andean foothills of Argentina, near Mendoza, at the San Jorge prospect. Systematic soil sampling has identified an Au-Cu porphyry deposit. This study also defined the metal zonation typical of these very large deposits.

The technology has also proven to be a very successful, cost effective and practical surface reconnaissance method for diamond explorers. In Australia, Botswana and Canada companies have used surface MMI geochemistry to prioritise geophysical and topographic targets identified as prospective for buried diamond-bearing intrusive pipes and dykes. The technique not only has a success rate in excess of 93% for correctly identifying potential hosts, but it has discriminated between different phases and compositional variations of the buried intrusives.

Further information on the MMI Process, Research Results, Technical Bulletins and numerous Case Studies are available in Mann et al., (1995, 1998a and 1998b) and on the website at [www.mmigeochem.com](http://www.mmigeochem.com).

## Analytical Performance

The analytical protocols developed for MMI extractions control many variables that normally constitute sources of error in other analytical methods, and enables the technique to achieve very high levels of precision and accuracy. All extractants are produced by WAMTECH from one location with strict control over the components used for manufacture. The performance of each is tested on standard soil samples prior to dispatch, to avoid any variation between the batches. All reagents have limited use-by dates and licenced laboratories undergo frequent QA/QC testing. Weights, volumes, temperature, time, viscosity and solubility are closely monitored and all equipment is used once and discarded to avoid cross contamination. The solutions have been specifically designed to optimize the ICP-MS/OES analytical method, and to present to the machine optimum analyte solutions for analysis thereby reducing interferences that can also introduce sources of error to the data. All solution development and testing is undertaken using routine ICP analyses at a commercial laboratory, thereby making new developments immediately available for industry application. Laboratories usually have specific staff dedicated to MMI work providing another level of continuity throughout the analytical process.

## Reproducibility

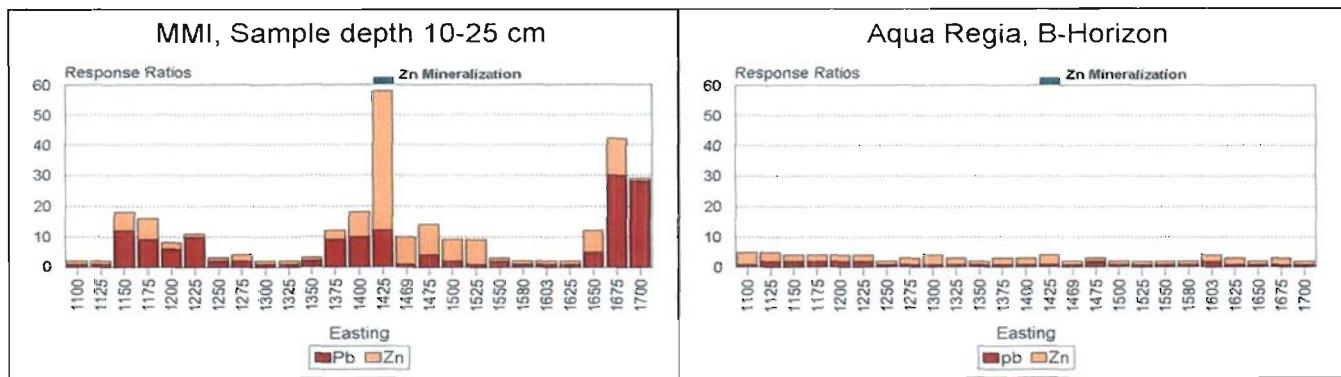

Numerous detailed studies have been undertaken to assess analytical reproducibility where repeat analysis of aliquot's of the same soil sample are tested and compared using the same analytical batch, and different analytical batches, over time. In both cases the technique has shown reproducibility characteristics as good and usually far better than total and other partial digest techniques (Mann et al, 1997, Reproducibility of data in the MMI Process).

Data from individual soil samples collected pre- and post rainfall at two field sites, one over blind Au mineralization and the other a barren control site, also showed excellent reproducibility (MMI Technical Bulletin TB04, Repeat Sampling Study, Mt Gibson, Western Australia).

## Independent Comparisons

During the course of its development, many comparisons have been undertaken between MMI and many other techniques. Below are data reproduced from an independent study undertaken by CAMIRO over a Zn rich VMS deposit in Ontario, Canada. The full study can be obtained from CAMIRO or viewed on the MMI Web site.

## O'Sullivan Lake Project, Ontario

Date: 2008.11.05

By: D.A. Beauchamp, P.Geo.

Figure 4

Page 1

Page 1

## Physiography

The terrain is generally low-lying, flat and somewhat swampy, with gentle slopes near the hills. There are few outcrops in the area and much of the terrain has a moderately thick cover of moss and peat with Labrador Tea and ferns. The trees consist of mostly conifers, mostly black spruce and a few cedars, and occasional white birch. A severe windstorm several years ago pushed caused some of the trees to fall over in an area called a blow down.

## Geology

The area is underlain by mostly mafic volcanic rocks of Archean age that have been intruded by Archean granodiorite and feldspar porphyry (Figure 4). Later Proterozoic diabase is also present in the area.

## Results

A total of 196 samples were collected on six grid lines at 100m line spacing over a period of three days by two soil samplers.

Of the elements analyzed, it was decided to concentrate on results for gold, copper, silver and cobalt. Since there is often a considerable amount of cobalt in pyrite, cobalt can usually give a good indication of the sulphide content present in the bedrock.

### Gold

The cumulative frequency diagram for the distribution of gold in the samples shows a moderately good lognormal distribution (Figure 5). Using traditional statistical methods, a mean of 0.11 ppb Au is obtained. Using Folk statistics (Folk, 1980) the mean is 0.07 ppb Au, but the median value is equal to the calculated background level at 0.05 ppb Au (Table 1).

In MMI sampling the background level for each element is calculated by averaging all samples at or below the first quartile, or 25<sup>th</sup> percentile.

### Copper

The cumulative frequency diagram for the distribution of copper in the samples shows a very good lognormal distribution, although the four highest samples from 8680 to 21,100 ppb may represent a separate anomalous population (Figure 6). Using traditional statistical methods we get a mean of 673.44 ppb Cu. With Folk statistics the mean is significantly lower at 250.13 ppm Cu, but the median value is 210 ppb Cu and the background level is set at 60.59 ppb Cu (Table 2).

### Silver

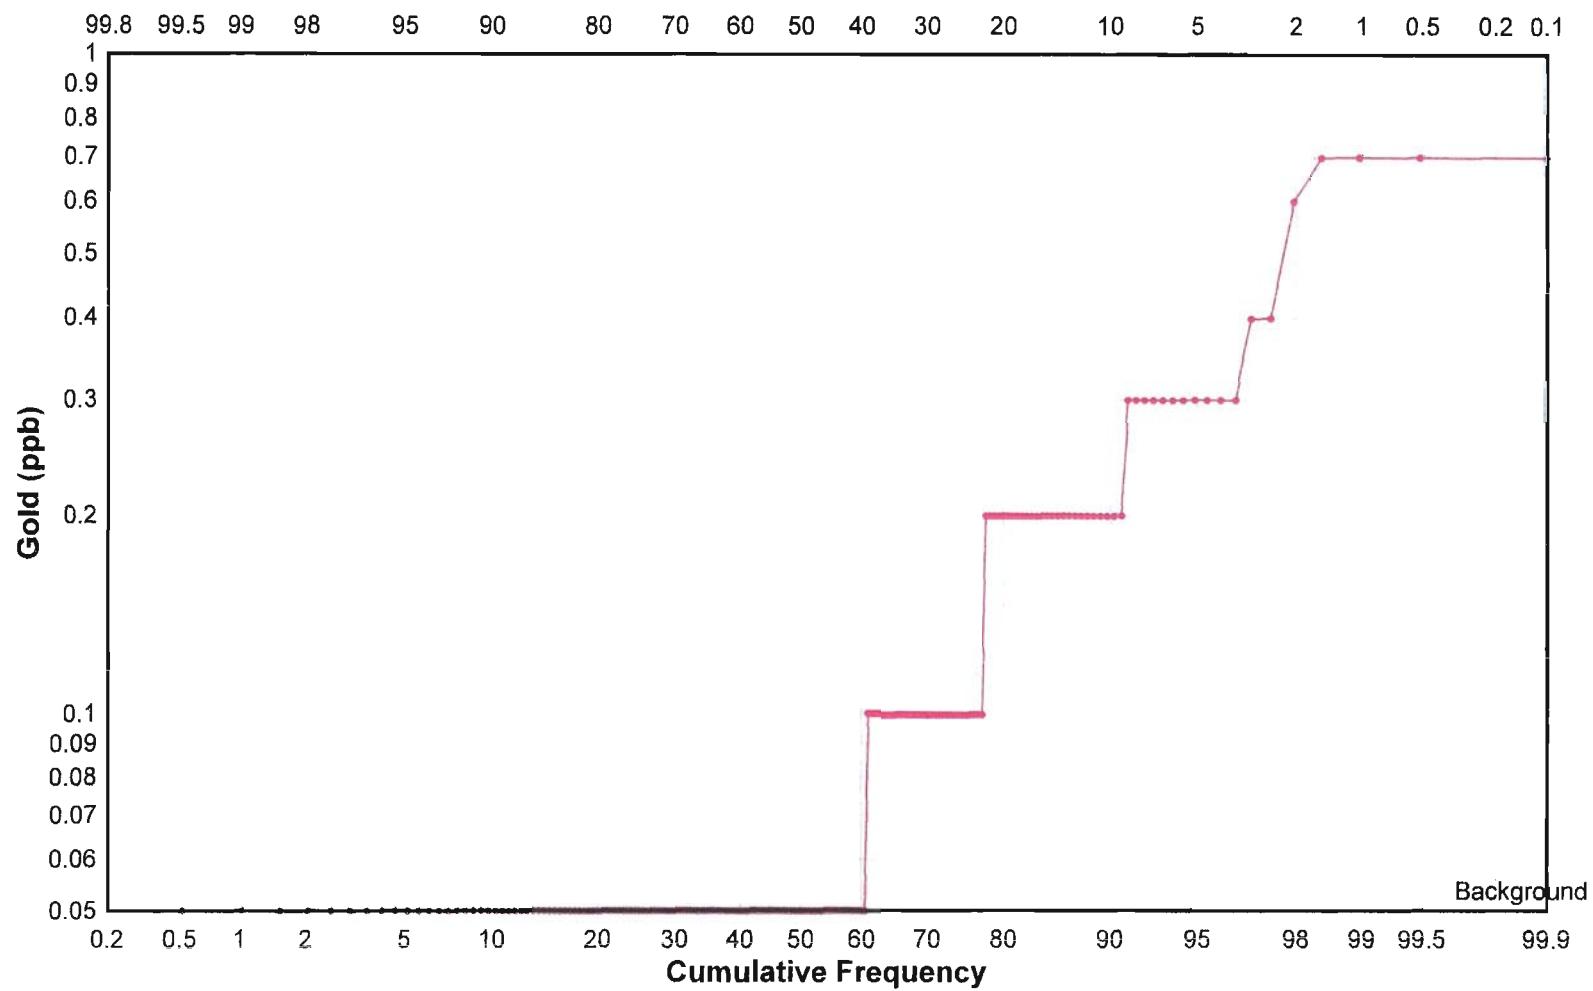

For silver, the cumulative frequency diagram in the samples shows a moderately good lognormal distribution, but the last sample at 83 ppb Ag is definitely anomalous (Figure 7). Traditional statistical methods give a mean of 3.61 ppb Ag reducing to 2.50 ppb Ag using Folk statistics. The median value is 2 ppb Ag but the background level is calculated at 0.50 ppb Ag (Table 3).

### Cobalt

The cumulative frequency diagram for the distribution of cobalt in the samples shows a very good lognormal distribution (Figure 8). Traditional statistical methods give a mean of 24.82 ppb Co reducing to 15.33 ppb Co using Folk statistics. The median value is 12.00 ppb Co but the background level is set at 2.50 ppb Co (Table 4).

### Interpretation

Interpretation of MMI data is best made by plotting the Response Ratio of each element as profiles. The Response Ratio is calculated by dividing the actual value of each element by the background value for the element. As described above, the background value is calculated by averaging the result for all samples less than the 25<sup>th</sup> percentile. The response ratios for each element can then be stacked along the profiles to determine the highest cumulative Response Ratio.

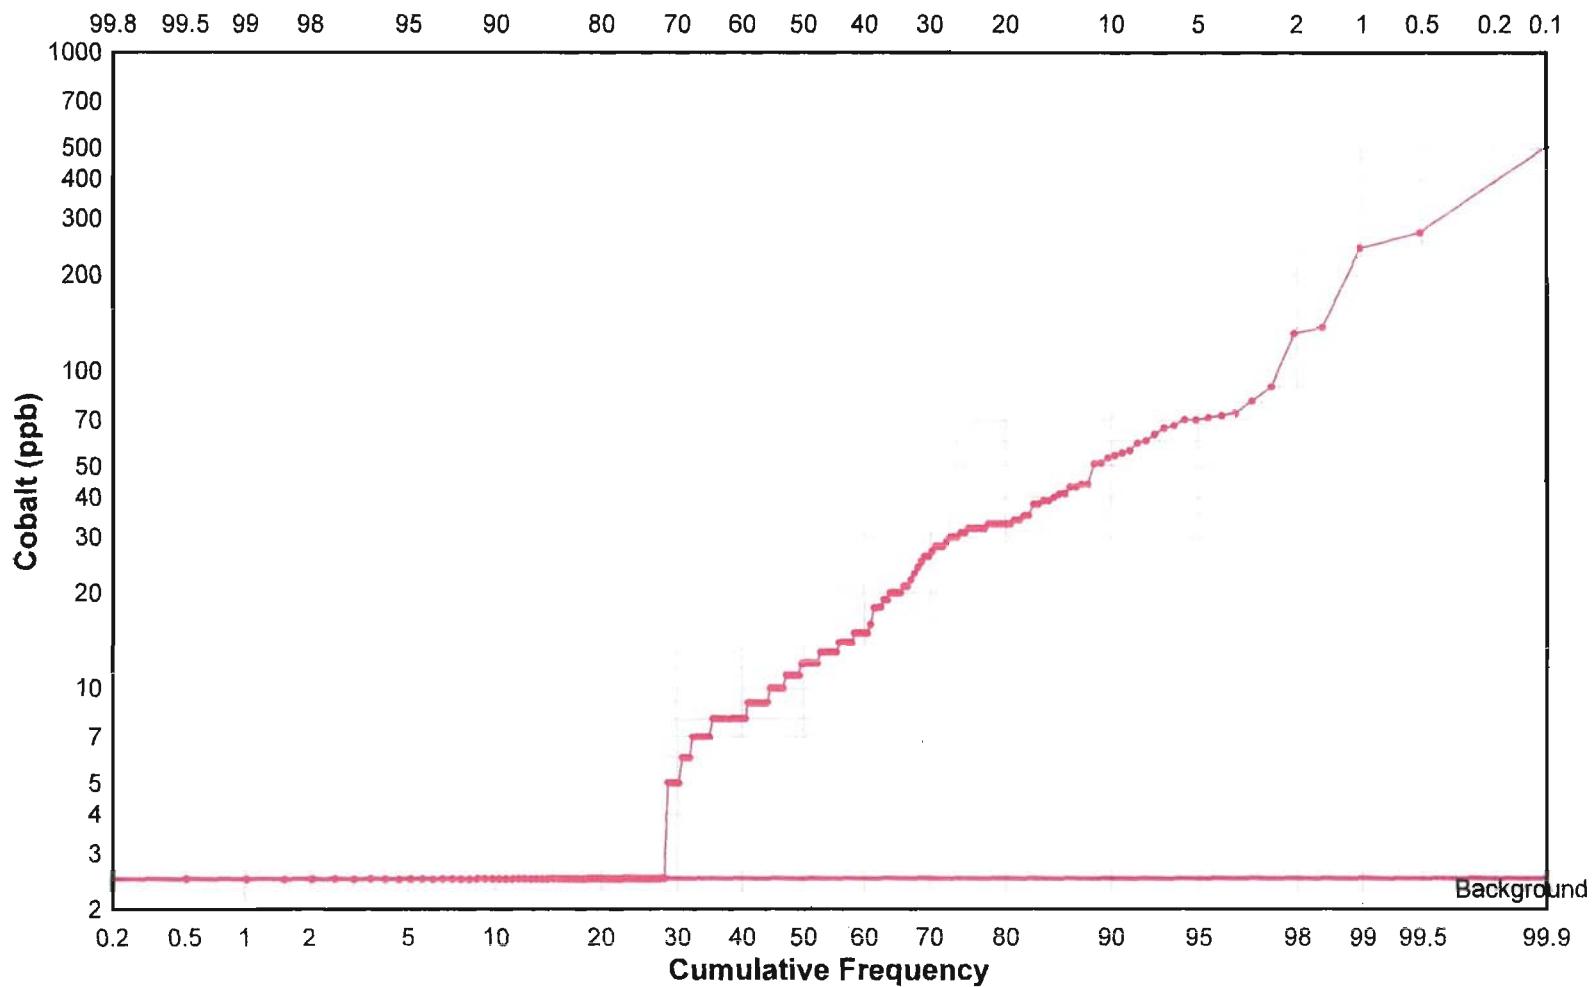

The data is plotted in Figures 9-20, each grid line split into two, for north and south sections. The sample spacing is approximate along the graphs.

The data shows considerable variation in the response ratios for each element and cumulatively. Grid line 2+00E North Section shows the highest response ratio for copper and cobalt, but the corresponding samples along L1+00E North Section are somewhat higher for silver but much lower for cobalt, copper and gold. L3+00E North Section shows some samples with higher values for gold but highly variable cobalt, silver copper.

Similarly, the corresponding results on the South sections are quite variable. The Base Line South Section has cumulative response ratios that are mostly less than 10 with the strongest component caused by cobalt. On the adjoining Line 1+00E South the response ratios are mostly 10 to 20, cobalt values are similar or lower, but copper, silver and gold are much higher. On line 2+00E South Section, the cumulative response ratios are quite variable, but cobalt is much higher. Lines 3+00E and 4+00E are of similar appearance but line 5+00E has generally lower Response Ratios.

The correlation coefficients are generally poor, ranging from -0.06 for cobalt and silver to 0.54 for cobalt and copper. The correlation coefficients between the rare earth elements are very good at 0.89 to 0.99. The only other elements that showed good correlation are iron and aluminum at 0.87. The correlation of 1.00 between cadmium and bismuth is of little significance since only 12 samples gave values of more than 1 ppb Bi.

## CONCLUSIONS

The soil survey carried out in the Kowkash area of the O'Sullivan Lake Project analyzed for mobile metal ions has returned results that are quite variable from one section to another and along the sections. The correlation coefficients between the elements analyzed are generally very poor for the elements of interest.

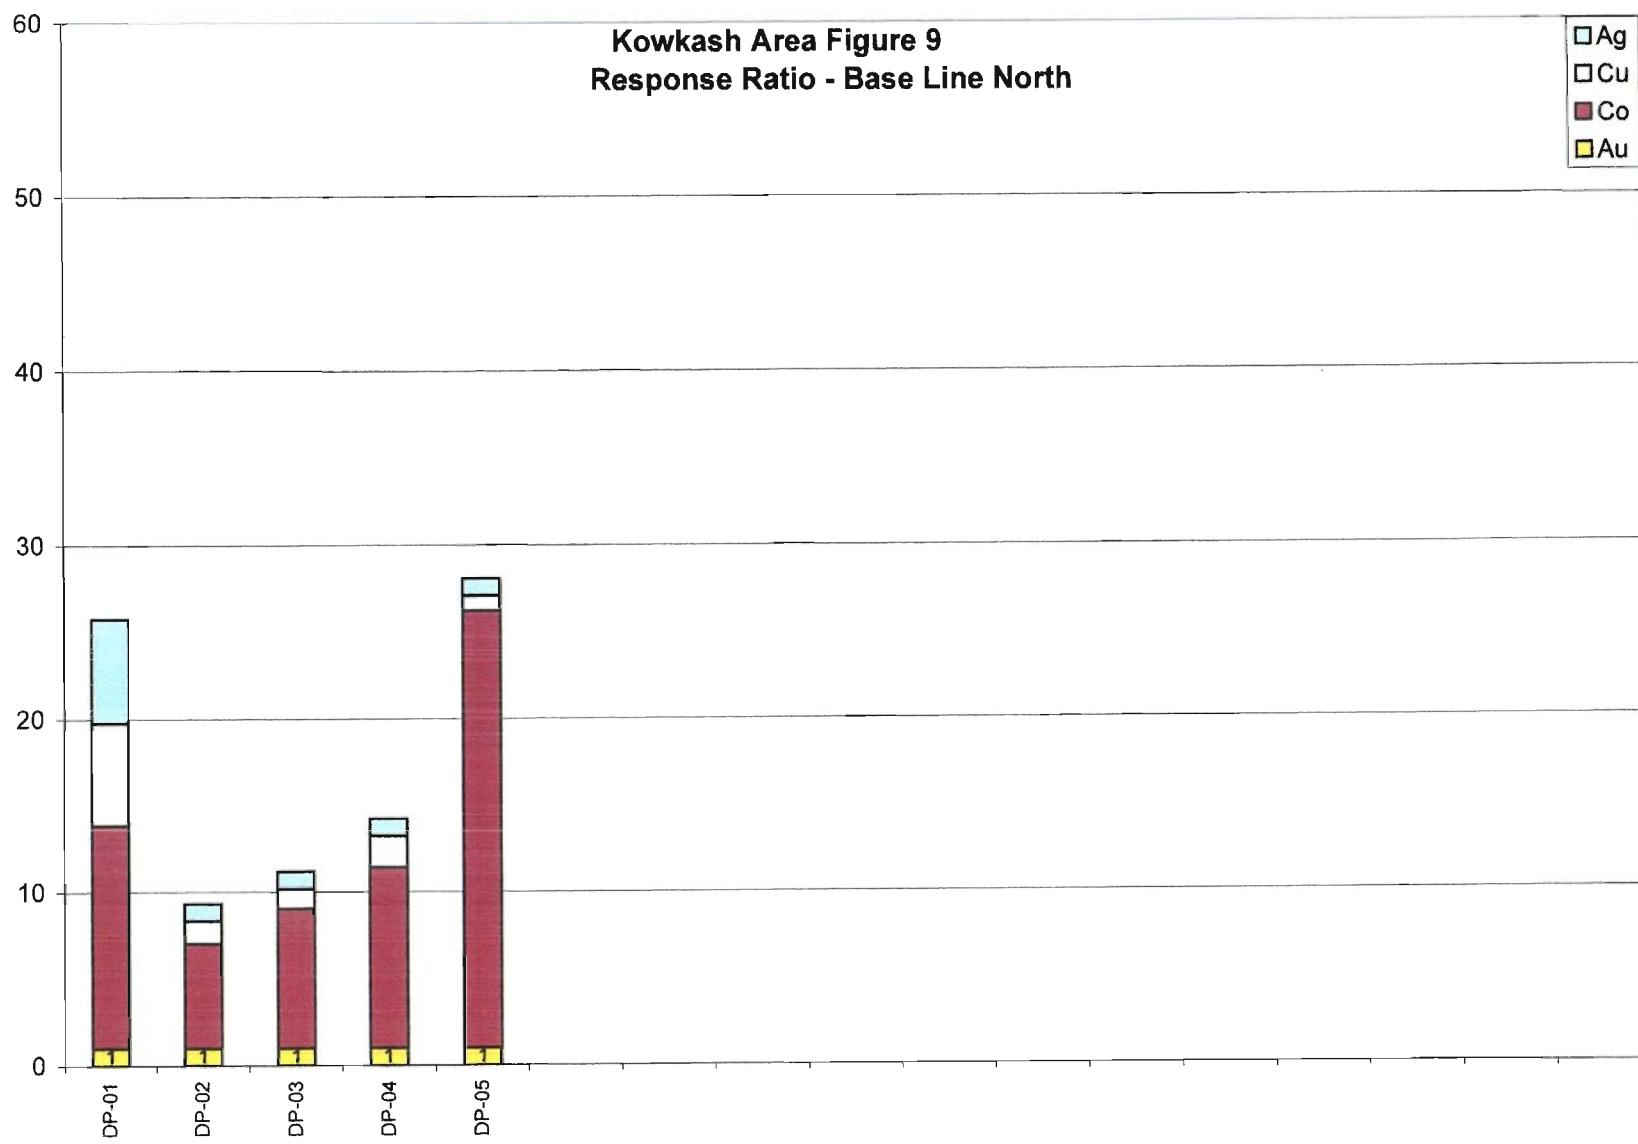

The results of the Mobile Metal Ion Survey have proven to be disappointing and the results cannot be used to outline any area that requires additional work or to help define target areas for exploration.

### **Appendix 3**

## Certificate of Analysis

Work Order: 090867

To: Superior Canadian Resources Ltd.  
Attn:  
Suite 207, 1039 17th Ave. SW  
CALGARY  
AB T2T 0B2

Date: May 18, 2007

P.O. No. : SUPERIOR CAN RES  
Project No. : DEFAULT  
No. Of Samples 20  
Date Submitted Oct 03, 2006  
Report Comprises Pages 1 to 6  
(Inclusive of Cover Sheet)

**Distribution of unused material:**

3 ts

Certified By : \_\_\_\_\_

Operations Manager

**ISO 17025 Accredited for Specific Tests. SCC No. 456**

Report Footer: L.N.R. = Listed not received I.S. = Insufficient Sample  
n.a. = Not applicable - = No result

\*INF = Composition of this sample makes detection impossible by this method

M after a result denotes ppb to ppm conversion, % denotes ppm to % conversion

Methods marked with an asterisk (e.g. \*NAA08V) were subcontracted

Subject to SGS General Terms and Conditions

The data reported on this certificate of analysis represents the sample submitted to SGS Minerals Services. Reproduction of this analytical report, in full or in part, is prohibited without prior written approval.
