PREUSSAG CANADA LIMITED TIMMINS WEST PROJECT GEOPHYSICAL SURVEYS 1981 Mag, VLF, HEM

RECEIVED

JUN 3 01981

MINING LANDS SECTION

INTRODUCTION

Magnetometer, VLF electromagnetic and HEM surveys were undertaken over a group of contiguous unpatented claims within the southwest part of Bristol township and the northeast part of Thorneloe township in the Porcupine Mining Division of the district of Cochrane (fig 1). Linecutting and geophysical surveys were initiated in January, 1981. Completion of the geophysics was in late June, 1981.

The surveys represent an initial stage in an overall objective to evaluate the gold potential of the claim group which is well situated geologically on the western extension of the prolific Timmins gold camp. Because of overburden coverage over a large part of the area it has not been amenable to evaluation by prospecting.

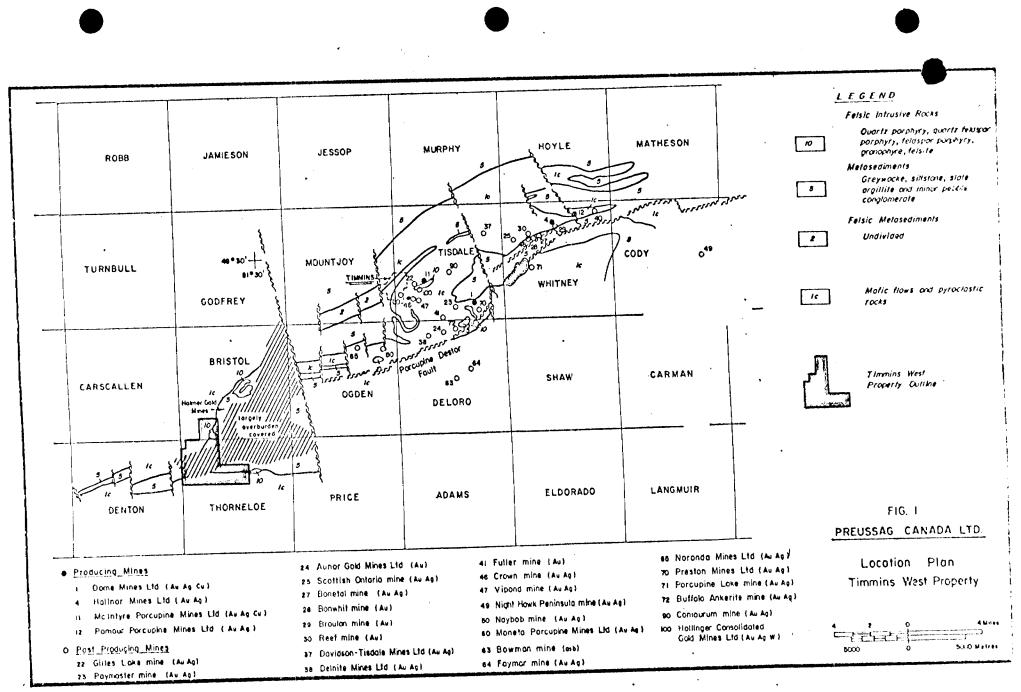

Property Description

The group consists of 109 contiguous claims as shown on fig 2. Recording dates range from December 6, 1977 to May 22,1981. The 25 earlier staked claims were staked and recorded by J. Croxall and D. Miller of Timmins and have been optioned by Preussag Canada Limited. The more recent claims, largely in Thorneloe township, were staked and recorded for Preussag Canada Limited. Geophysical surveys cover only claims as listed in appendix.

Location and Access

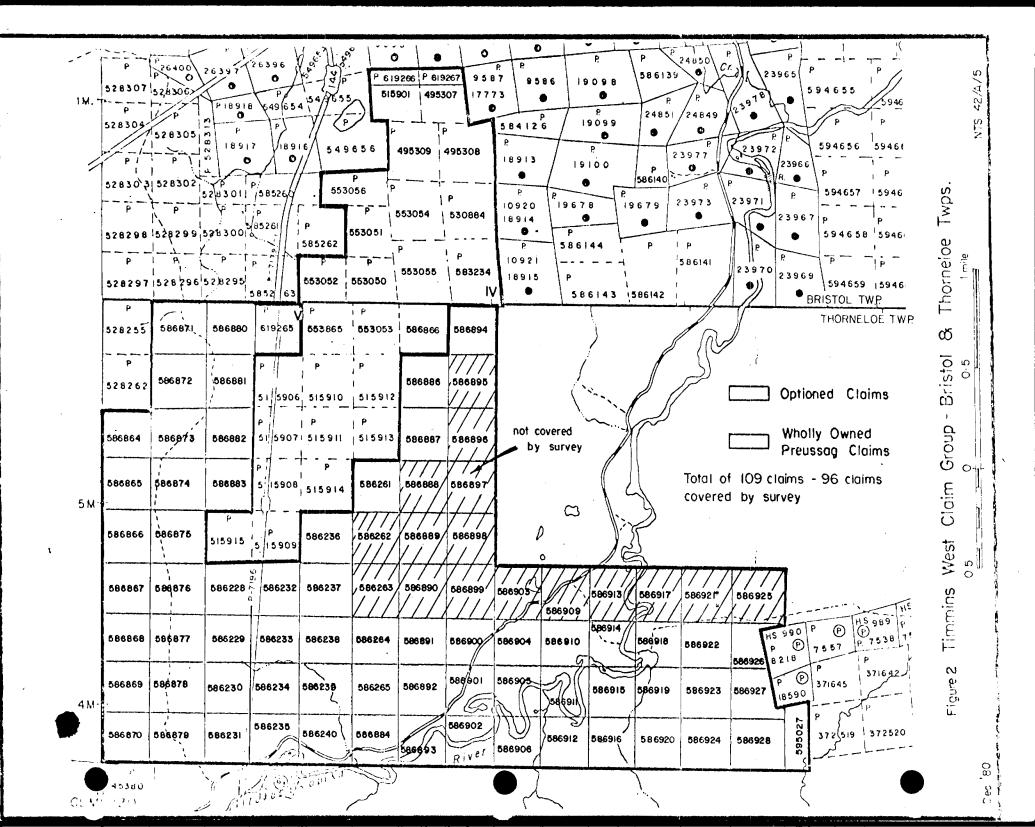

The property is located in northern Ontario, 20 km southwest of the city of Timmins; a main mining and population centre in the area.

The property is readily accessible from Timmins by way of highways 101 and 144. The latter crosses the western part of the claims. Access roads for lumbering

Ν.

.

operations make ease of activities within the property quite good. Most parts are within easy walking distance.

Topography is flat except for outcrop areas in the Bristol township claims. Otherwise spruce swamps, cedar swamps and some spruce covered sand plains dominate.

Results of Previous Investigations

The first recorded work on the property was undertaken by Rusk Porcupine Mines in 1942 on what are now claims 495307, 495308 and 495309 in Bristol township. Pits, trenches and 18 diamond drill holes (6,500 feet) were completed. No assay results from the drill holes are available, however channel samples in carbonatized andesite produced assays of: 4.0 ft of 0.71 oz/T Au; 2.5 ft of 0.43 oz/T Au; and 3.0 ft of 0.24 oz/T Au. (ref. ODM vol 66, pt. 7, 1957).

Various geophysically directed programs were undertaken over scatered parts of the present property from 1951 to 1962 as follows:

1 - 1951 Dominion Gulf did a mag survey north and south of the Tatachikapika River in Thorneloe Township. Three holes intersected iron formation.

2 - 1959 - 1962 Hollinger drilled at least 20 holes as follow up to magnetometer and EM surveys in Thorneloe and Bristol Townships. A variety of rock types such as basic volcanics, ultramafics, porphyries, iron formation and slates were intersected. Assays are not available, but massive pyrite and pyrrhotite stringers and carbonated metasediments with quartz and pyrite are recorded.

No recent exploration has been undertaken on the property itself, but over the last ten years there has been intermittent activity on the Holmer property immediately to the north where a shear zone up to 150 feet wide in carbonated metavolcanics carries gold in quartztourmaline veins.

-4-

Survey Specifications

The surveys were completed on picket line grids as shown on Maps. Baselines were oriented parallel to what is believed to be the regional trend of the lithologics. Picket line spacings are at 120 metres.

-5-

The survey was carried out by Mr. F.A. Hodgkinson, assisted by Mr. Beaulieu and Mr. G. Mason-Apps. Magnetometer Survey - Readings were taken at 30 (a) metre intervals along the picket lines using a Scintrex MP-2 (see appendix) proton precession magnetometer. Readings were corrected for drift by tying into the baselines which had been read and corrected previously by using the looping method of baseline correction. VLF Survey Readings were taken at 30 metre stations (b) with the Geonics EM-16 (see appendix) to record the In-Phase and Out-of-Phase components. The Cutler Maine transmitter at 17.8 k Hz was utilized for the entire Signal strength from Panama station was extremely survey. weak and hence could not be used for Baseline "B" in spite of its ideal locaion. Readings on Baseline A and

B were taken with the operator facing south in both instances.

(c) HEM Survey - Readings were taken at 30 metre stations with the Apex Parametrics MaxMin II EM system (see appendix) in the horizontal loop mode. A coil separation of 120 metres was used and readings at 444 Hz and 1777 Hz were recorded. Since the topography is fairly level no corrections were necessary.

.../6

Survey Results and Interpretation

(a) <u>Magnetics</u> - Contoured magnetics are illustrated on maps 2a, 2b, 2c.

The grid A area (maps 2a, 2b) is dominated by a series of parallel and en echelon mag highs along and adjacent to the baseline from line 1680E to the east The strongest and most continuous of end of the grid. these linear mag features exists from line 2160E to line 5880E with local intensities to greater than 42,000% above background at two locations - namely at the baseline on lines 3240E to 3480E and at 150N on line 5280E. The magnetic intensity and linearity of this feature is typical of that caused by magnetite iron formation. Steep gradients suggest shallow depths locally (see line 5280E). However, on line 3360E not only is a deeper source interpreted from shallower gradient but the broad nature of the anomaly is also more consistent with a thickening, probably by folding.

The en echelon mag high from L 1800E to L 2520E has similar characteristics to the previously mentioned feature and is also attributed to a magnetite iron formation source . It is interpreted as either an isoclinally folded repetition of the main magnetite iron formation zone or else a faulted segment. If the latter interpretation is taken, the fault would have to strike at N70W in order to achieve the noted geometric relationship.

A third linear mag feature is at 240N on lines 3000E to 3360E. It is another stratigraphic feature of iron formation character but of short strike length.

A series of north striking weakly magnetic features marked by low amplitude (+1000% above background) isolated peaks and ridges coincide with what are interpreted as diabase dikes. These occur randomly across the claim group. The more prominent dike related magnetics occur along or parallel to lines 240E, 480E, 4080E, 4440E and 5760E. Other possible dikes which occur as more

.../7

-6-

subtle features are along Ll20E, Ll920E, L2640E, L3240E, L3840E and L5160E.

The only other notable magnetic feature on grid A is an irregular pattern in the northwest under claims 586865, 586874, 586875 and 515915. The bullseye pattern with anomalies to 1500 γ above background suggests the underlying presence of ultramafic intrusives such as are found to the immediate north and are responsible. for the pattern seen on map 2c.

Magnetics of grid B are dominated by a linear bullseye pattern along the entire length of the grid from along the baseline to the west edge of the grid. The 60,000 % contour essentially marks the eastern limit. To the east of this the magnetics are flat with not more than 100 % variability throughout except where magnetic ridges corresponding to the presence of diabase dikes are seen (e.g. through the centre of claims 586236, 515914, 515911 etc and along the west side of claims 586887, 586886 etc).

The bullseye pattern with highs locally to 6000 above background correspond to a N30E trend and confirms the presence of pyroxenite intrusives such as that noted in outcrop at 30E on L3480N. These intrusives are apparently located somewhat randomly within non magnetic rocks of volcanic origin such that magnetics between the pyroxe-nitic intrusives decrease to background intensity. b) VLF - Results of the EM-16 VLF survey are plotted as profiles on maps 3a, 3b and 3c. Conductor traces are illustrated by solid lines.

In the Grid A area a network of more than forty parallel to sub-parallel conductors cross the entire area from west to east. None have a configuration typical of bedrock conductors close to the surface. However,

.../8

-7-

four (lettered A, B, C and D) show characteristic profiles of deeper bedrock conductors with moderate to good conductivity. Their symmetrical profile shape is typical of near vertical sheet like bodies. Qualitiative data is supplied by the HLEM data which is discussed in the next section.

-8-

The remainder of the conductors are typical of sources having weaker conductivity. Peak to trough distances of greater than 120 metres and asymmetry of the profile suggest causative features related to variable thicknesses of conductive overburden (i.e. buried overburden filled valleys and edge effects). Nevertheless, the conductive trends which range up to 1600 metres in length are sometimes parallel to magnetic trends, and hence could be related to either bedrock lithologies which are less resistant or to shears.

VLF EM results over Grid B are erratic and peaky because of the presence of outcrop hummocks and sand hills separated by swamps and overburden filled bedrock troughs. Conductors are mostly sub-parallel conductors and have characteristics typical of edge effects along either outcropping and buried outcrop knobs, creek bottoms or overburden troughs. Except in certain instances, their continuity from line to line has been interpreted somewhat arbitrarily assuming a strike direction subparallel to the baseline. Poor directional coupling of the grid in relation to the location of the Cutler transmitter station has helped to compound the interpretational problems in this type of terrain.

Typical of grid B conductors is the one which coincides with the beaver pond on line 3000N at 300E. This feature traces the creek valley both north and south of the pond and can be attributed to the overburden filled valley which is mapped between outcrop hills on each side. A weak shear in the underlying trough could be responsible for some enhancement of the anomalous amplitude but

.../9

overburden thickening is the dominant force.

Qualitative appraisal of these weak conductors will be discussed in the next section covering HLEM results.

c) HLEM - Horizontal loop EM results are plotted as profiles on maps 4a, 4b, 4c and maps 5a, 5b, 5c for 444 hz and 1777 hz respectively.

In the grid A area (maps 4a, 4b, 5a and 5b), four bonafide bedrock conductors are detected in the central part of the grid to the north of the baseline. Anomaly A is 110 metres long and is very narrow with a vertical or near vertical dip. Estimated depth is approximately, 40 metres. There is no mag association and conductivity thickness values are low as evidenced by the rapid decrease in IP/OP measured at 1777 hz and at 444 hz.

Anomaly B is directly on strike with anomaly A and is probably on the same horizon. As shown on maps 4a and 4b it is composed of two thickenings for a 2000 metre strike length. It varies from 0 to 15 metres in thickness. The thickest and most conductive part of the body is at the eastern end on line 3240E at 240N where it is calculated to have greater than 18 mho conductivity -thickness and to have a 60 metre depth.

Immediately to the east on line 3360E a depth estimate of greater than 44 metres and a conductivity-thickness value of greater than 10 mho is calculated. Although there is no magnetic response indicated for anomaly B, the portion from L2880E to L3360E has a linear mag high of greater than 12000 γ parallel and flanking at 30 metres south.

Anomaly C is a 360 metre long conductor centred at 40N on line 3000E where is has its maximum calculated thickness of approximately 20 metres. Conductivitythickness is approximately 30 mho and depth is 40 metres,

-9-

It lies 150 metres to the north and parallel to the strong magnetic feature producing the +4200 ° mag high of map 2b.

Anomaly D, which defines a short 20 metre wide bedrock feature at 45N on line 3840E shows up on only two picket lines. It has a conductivity-thickness value of greater than 30 mhos and is estimated to be less than 45 metres deep. It appears to be on strike with anomaly C but a direct magnetic correlation of up to 5000% suggests a different causative source.

Only two other types of anomalous responses are noted for Grid A - namely weak out-of-phase responses . and local high in-phase peaks. The former type of response is widespread and is illustrated on maps 4a, 4b, 5a and 5b as dashed lines defining axes of weak out-ofphase trends. They vary from single line anomalies to ten line anomalies and are typically quite readily The lack of in-phase response and decrease traceable. in intensity from 1777 hz to 444 hz puts their cause in the category of overburden filled bedrock troughs adjacent to bedrock ridges. The lack of significant response at 444 hz confirms this interpretation although bedrock shears could be coincident with some and could be partially responsible for the trough and ridge configuration of the bedrock surface.

VLF anomalies are seen to coincide exactly with the weak HEM responses.

Positive in-phase responses occurring from L1680E to L3480E and from L4680E to L5760E are the only remaining anomalous responses. These are directly attributed to magnetite in magnetitic iron formation. The fact that amplitude of the readings remains constant at both 444 hz and 1777 hz and that no anomalous out-of-phase response is produced substantiates the interpretation of narrow magnetic, non-conductive tabular bodies. Positive 1P responses are produced only when either the transmitter or receiver is directly over the magnetic body. Unlike a true conductor, no anomalous readings are noted when the body is straddled by the two instruments.

-10-

For Grid B (maps 4c and 5c) anomalous responses are produced by effects of variable overburden thicknesses and by effects of magnetite in the bedrock. As with Grid A, overburden features are defined by negative out-of-phase responses. The majority are parallel or sub-parallel to the regional stratigraphy and are hence believed to be related to a bedrock topography dominated by differences in hardness of the volcanic and intrusive units. Conductors to the south of the baseline from L1320N to L3120N coincide remarkably well with the south edge of pyroxenite intrusives. Two others in the vicinity of 810E on L1800N correspond very closely with an interpretation conforming to a bedrock ridge along the diabose dike defined by magnetics on map 2c.

The remaining anomalous feature of Grid B coincides with highway 144 from 360N to 1560N and has a character typical of a grounded wire. The negative out-of-phase response is normal for an overburden response but the flat bottom to the profile indicates a flat cylindrical source. It is concluded that the grounding of the wire causes it to take on the conductivity character of the overburden or hence only an out-of-phase response.

Summary

Results of the mag, VLF and HEM surveys illustrate a simple pattern of magnetics and conductivity as follows: (a) grid A shows a predominant E-W lithologic trend dominated by a strong mag feature over the eastern twothirds of the grid. The intensity of the magnetics is typical of magnetic iron formation for the most part. However, an ultramafic flow or intrusive is interpreted for a shorter mag feature at the north edge of the main mag high;

(b) magnetics in the central part of grid A indicate either a thickening by folding or else a repetition of magnetic horizons;

.../12

(c) associated with the wide mag zone of grid A are
 four moderate bedrock conductors with little to no coinciden
 magnetic response;

(d) diabase dikes show up as weak north trending magnetic ridges;

(e) weak conductive trends conforming to edges of bedrock ridges occur throughout the gird;

(f) no conductors of merit are noted on Grid B. However, a number of weak features related to buried bedrock topography are recognized;

(g) irregular magnetic features of Grid B are coincident with pyroxenite sills which are partily exposed in the northern part of the grid. Diabase dikes show up as magnetic ridges striking due north.
