EXPLORATION OF THE SCHRYBURT CARBONATITE COMPLEX

G. Erdosh

March, 1977

International Minerals & Chemical Corporation (Canada) Ltd. Toronto, Ontario M5E 1J4

EXPLORATION OF THE SCHRYBURT CARBONATITE COMPLEX

G. Erdosh

International Minerals & Chemical Corporation (Canada) Ltd.

INTRODUCTION

A group of 155 claims were staked in October, 1975 to cover a possible carbonatite-alkalic igneous complex, the presence of which was predicted from an outstanding circular airborne magnetic anomaly of about $3\frac{1}{2}$ miles in diameter (1-mile aeromagnetic series, map 938G, ODM-GSC). No record of drilling the complex appears in the Mining Recorder's assessment files but previous exploration conducted detailed ground magnetic survey and tested the complex by a number of shallow trenches.

The present program included an attempted geologic mapping, soil survey, and reverse circulation drilling.

LOCATION, ACCESS, TOPOGRAPHY

The claim group is located 75 air-miles north of Pickle Lake, Ontario where the nearest airbase is available. The complex adjoins Schryburt Lake to the east. The only access is by air from Pickle Lake by float- or ski-equipped aircrafts which can land on Schryburt Lake.

The topography is flat with occasional small sandhills, consequently wet muskeg cover with black spruce and tamarack is extensive. The slightly higher grounds are probably mainly sand and gravel, covered by spruce, in places birch, and less commonly poplar and pine. Glacial boulders are common throughout. There were no roads or trails on the property previous to this program.

CLAIMS

The 155 claims originally staked are listed in Appendix A. Since these were staked in the late fall of 1975 and geologic work was done during the summer of 1976, due to wet conditions on the property it was not easily possible to conduct drilling before assessment work was due in October 1976. Therefore, a 6-month extension was requested so drilling may be undertaken after freeze-up. The extension was requested for a reduced claim group of 82 claims listed in Apprendix A, also.

Assessment work here is filed for 34 claims.

PERSONNEL

Geologic and soil surveys during July 1976 were conducted by the writer with the assistance of W. W. Ray. Drilling in January 1977 was done by Bradley Bros. Drilling Company of Noranda, Quebec; the work was supervised and geologic logging was done by the writer.

-2-

Analytical work for phosphate, x-ray and scintillation determinations and mineralogical examinations, was done in IMC's own laboratories in Libertyville, Illinois. Semi-quantitative spectrographic analyses were performed by American Spectrographic Laboratories, San Francisco, California.

GEOLOGY

Geologic field examination and a cursory soil and trench sampling were done during July 1976 by the writer and his assistant. Most trenches of the previous exploration program were visited, examined and sampled, and most of the higher ground was traversed to locate rock exposure.

There was only one definite rock exposure found over the carbonatite-alkalic complex near the east boundary of the property along the river bank just north of the Schryburt Lake outlet (see map in pocket). This exposure confirmed the existence of a carbonatite complex and is an unweathered medium-grained, sugary textured, nearly white, heterogeneous calcite carbonatite with 5-10% acicular green actinolite, few percent magnetite, minor pyrite/ pyrrhotite and 10-15% apatite. The exposure is very small and made up of carbonatite slabs along the river bank and river bed over an area of 15-20 feet. The

-3-

carbonatite includes numerous irregular mafic xenoliths showing the explosive nature of the intrusion.

The series of old trenches in the northeast, northwest and west parts of the claim group were carefully examined and sampled (see map). Only in a few cases was it fairly certain that the trenches were in rock in place. In most instances this was indefinite; although the rocks in the trenches were all of local derivation, they appeared to have moved somewhat and could not be called exposures in place. All rocks in the trenches are highly weathered.

The rocks in the trenches are carbonatite, quite variable in composition from white calcite carbonatite through vermiculite-rich or magnetite-rich rocks to mafic-rich carbonatite. All rocks have been subjected to strong physical but little chemical weathering and now they are decomposed into semi-consolidated to unconsolidated sand-like material, still high in calcite.

Drilling further confirmed the existence of the carbonatite complex.

GEOCHEMICAL SURVEY

At the commencement of the exploration work it was known to us that rock exposures are rare over the complex; therefore it was decided to test by analytical techniques possible residual soils and all local rock that may not be far removed from its source. Phosphate

-4-

tests were considered one of the most important tests because phosphate values may give a clue of possible residual concentration by chemical weathering, which was one of the objectives of the program.

Therefore, during the field work in July soil and rock samplings were also taken which were analyzed in IMC's laboratories for phosphate and acid residues. Due to the fact that few areas qualified as near bedrock or possible residual soil, only 10 samples were analyzed. The analytical results are given in Appendix B. Looking at the analytical results of carbonatitic soil and rocks it may be concluded that no concentration of non-weathering minerals occurred, such as apatite in the soil. The weathering producing the soil was entirely or dominantly physical weathering.

PURPOSE AND RESULTS OF DRILLING

The economic potential of the carbonatite complex was tested by drilling six widely-spaced holes. The purpose of this drilling was two-fold; (a) to test a possible residual accumulation over chemically weathered carbonate-rich rocks and (b) to test the bedrock itself.

Being well-acquainted with carbonatitic rocks from other similar complexes, it was advisable to forfeit the more trouble-free and less-expensive standard diamond

-5-

core-drilling technique for reverse circulation drilling using tricone bits. Furthermore, this drilling technique has the additional disadvantage of yielding tiny rock chips only, making field identification and geologic studies very difficult.

Nevertheless, to test unconsolidated or semi-consolidated residual deposits reverse circulation is still the best technique. Even for testing bedrock this is better than core drilling since carbonate-rich rocks in the cool moist northern Canadian climate are generally rotted and criss-crossed by solution channels and cavities near the surface, resulting in poor core recovery.

The criteria of selecting the drill sites were varies; for the first four holes topography in conjunction with magnetic values was used as a guide. Again from previous experience, low topography may, and probably is, an indicator of solution in the carbonate-rich rocks where present. And residual accumulation is expected in the deepest solution depressions, now of course buried by glacial overburden.

After drilling the first four holes it was found that chemical weathering over the carbonate-rich rocks is only present in <u>hole SC-1</u>. If ever it was present elsewhere, it has been scraped off by glaciation. A thin layer of physically weathered disintegrated carbonatite, now a

-6-

sand, may be the only weathering product over bedrock. This is a few feet thick.

The last two holes were designed strictly for testing bedrock. <u>SC-5 was</u> drilled on a high magnetic anomaly and <u>SC-6</u>, a last test on the outermost ring in the onion shell of the carbonatite complex.

The objectives of drilling were achieved but with disappointing results. The overburden was found to be shallow everywhere and chemically weathered residual accumulation on bedrock was only found in one drill hole, SC-1. Here the accumulation is about 30 feet and phosphate analysis of this section resulted in $17.5\% P_2O_5$. The bedrock under this residual is also higher in phosphate than elsewhere, in the $7\% P_2O_5$ range. Since drilling was not detailed enough, it is not known how extensive this residual accumulation is.

All six holes intersected calcite carbonatite of two major types: (a) white mafic-poor rock with predominant calcite and minor magnetite, apatite, phlogopite, pyritepyrrhotite and actinolite and (b) a similar rock but with significant mafic constituents (25-60%) of pyroxene or amphibole, high phlogopite and magnetite. Calcite still remains relatively high.

Due to the nature of drilling it is not possible to tell rock structures, but all carbonatite appears to be well-banded and, it is presumed that structures are near vertical.

-7-

ASSESSMENT CREDIT REQUESTED

The assessment work on the Schryburt property consists of drilling, geologic field work with some soil sampling, geologic office work, drilling supervision and core logging, assays, and laboratory studies.

The calculation of credits is as follows:

Drilling, 960 feet @ l day/ft.	960	days
Geologic field work, 2 men, 3 days @ 7 days/man-day	42	days
Office work, etc., 4 days @ 7 days/man-day	28	days
Drilling supervision, 12 days @ 7 days/man-day	84 1,114	days days

Analytical:

$(10)P_2O_5$ and insoluble analyses, (16)P_2O_5 analyses, = 26 @ \$9.50/sample	\$ 247.00	
12 SQS analyses @ \$28.00/sample	336.00	
33 X-ray diffraction analysis of insoluble fraction @ \$56.00/sample	1,848.00	
(18) Scintillation analysis @ \$8.00/sample	$\frac{144.00}{\$2,575.00}$	
At \$15.00/day credit requeste	ed =	
Total credit requested =		1,

171 days ,285 days

REQUESTED DISTRIBUTION OF CREDITS

A credit of 20 days/claim is requested for the following 19 claims, for a total of 380 days:

Pa.	438144	Pa.	438340
Pa.	438145	Pa.	438341
Pa.	438158	Pa.	438342

SUBJECT Schryburt Lake Carbonatite, Ontario

We have examined selected interval samples from the Schryburt Lake carbonatite.

Phosphorus analyses and semiquantitative spectrographic analyses of these intervals are shown in the attached Tables 1 and 2. Phosphorus values occur as apatite. The highest assay, 19.6% P_2O_5 , indicates about 50% apatite.

Carbonates were removed by acid leaching. The numeral compositions of the insoluble residues are shown in Table 3. Pyrochlore is probably the main source of niobium. In addition the perovskite may also contain a minor amount of niobium as in the perovskite group member latrappite.

Relative counting rates were obtained from selected sample intervals. These rates are shown in Table 4. These rates are for alpha particles only. For comparison the following rates were determined under the same conditions:

blank planchet	7 cts/50 min.
agricultural limestone	10 cts/50 min.
Florida 72 BPL concentrate	251 cts/50 min.

Counting rates equivalent to Florida phosphate concentrates were obtained on intervals from holes SC-1 and SC-6.
